ABSTRACT
This paper proposes an unsupervised, batch-type, class-based language model adaptation method for spontaneous speech recognition. The word classes are automatically determined by maximizing the average mutual information between the classes using a training set. A class-based language model is built based on recognition hypotheses obtained using a general word-based language model, and linearly interpolated with the general language model. All the input utterances are re-recognized using the adapted language model. The proposed method was applied to the recognition of spontaneous presentations and was found to be effective in improving the recognition accuracy for all the presentations. The best condition was found to be using 100 word classes, and in this condition 2.3% of the absolute value improvement in the word accuracy averaged over all the speakers was achieved.

1. INTRODUCTION
Although speech of reading written texts can be recognized with a high recognition accuracy using state-of-the art speech recognition technology, the recognition accuracy of freely spoken spontaneous speech is still low. For example, currently, mean recognition accuracy of spontaneous presentation recognition using “Corpus of Spontaneous Japanese (CSJ)[1]” can only reach roughly 70%[2]. The principal cause of the problem is a mismatch between trained acoustic/language models and input speech due to the limited amount of training data in comparison with the vast variation of spontaneous speech. Spontaneous presentation utterances are both acoustically and linguistically variable according to speakers and topics. To cope with this problem, automatic adaptation is essential for both acoustic and language models.

Adaptation techniques can be classified into supervised and unsupervised methods. Since unsupervised methods can use recognition data itself for adaptation, they are more flexible than supervised methods. However, unsupervised methods are usually more difficult to develop than supervised methods, especially for spontaneous speech having a relatively high recognition error rate. Supposing that the presentation recognition is performed off-line, we have recently investigated a batch-type unsupervised acoustic model adaptation for this task, in which first all the presentation utterances are recognized using a speaker-independent model, and then a model adapted using the recognition results is used to re-recognize the utterances. This process is repeated until recognition results converge. We have achieved roughly 5% improvement of word accuracy by this method[2]. Although various useful unsupervised acoustic model adaptation methods have been proposed, unsupervised language model adaptation has not proved to be highly successful in improving recognition accuracy[3]. This is because the language model space is usually very sparse and therefore it is very difficult to obtain reliable information from recognition results with a relatively high recognition error rate.

In order to cope with the sparseness of the language model space, class-based language model adaptation methods have been proposed[4, 5]. However, they have never been used for unsupervised adaptation in spontaneous speech recognition.

This paper proposes a class-based batch-style unsupervised language model adaptation for spontaneous speech recognition and presents its effectiveness in spontaneous presentation recognition using the CSJ.

This paper is organized as follows. Section 2 describes the unsupervised language model adaptation method. In Section 3 experimental conditions are described. In Section 4 we describe and discuss recognition experiments performed using our adaptation method. Finally, in Section 5 the main conclusions are presented.

2. UNSUPERVISED LANGUAGE MODEL ADAPTATION
Figure 1 shows the overview of the proposed class-based unsupervised language model adaptation method.
3.2. Language model

The general language model (G-LM) consists of word-based bi-grams and reverse tri-grams. Bi-grams and reverse tri-grams are used for the first path and the second path of decoding, respectively. Unseen $n$-grams are estimated using the Katz’s back-off smoothing technique[7]. The approximately 35k words that appear twice or more in the training data set are selected as vocabulary words.

The class-based language model (C-LM) consists of class-based bi-grams and reverse bi-grams. Probabilities of class transition and word occurrence in each class are estimated using the recognition results. Therefore, the vocabulary covers only the words appearing in the recognition hypotheses.

The adapted language model (A-LM) consists of word-based bi-grams and reverse tri-grams. The reverse tri-gram is obtained by interpolating between the reverse tri-gram of G-LM and the reverse bi-gram of C-LM.

All language models are made using the SRI Language Modeling Toolkit[8].

3.3. Acoustic model

The acoustic features are 25 dimensional vectors consisting of 12MFCC, their delta and delta log energy. The CMS (cepstral mean subtraction) is applied to each utterance. A speaker independent acoustic model is made using 455 presentations, having a length of approximately 94 hours, taken from the training data set. The model is a tied-state triphone HMM having 3k states and 16 Gaussian mixtures in each state. HTK v2.2 is used for the acoustic modeling.

4. EXPERIMENTAL RESULTS

The Julius v3.2 decoder[9] was used for speech recognition. Insertion penalty and language model weight were optimized for the recognition condition using the G-LM.

Figure 2 shows the test-set word perplexity as a function of the interpolation coefficient $\lambda$ at various conditions of the number of word classes; 50, 100, 500, and 1000. In the “w2gram” condition, the C-LM is equivalent to the word-based bi-gram and reverse bi-gram modeling with no word classes. The perplexity decreases with adaptation in all the word-class conditions. When a C-LM with 500 classes or more is used, the perplexity becomes almost a half of that before adaptation at the best condition of the interpolation coefficient $\lambda$.

Figure 3 shows the word accuracy averaged over all presentations as a function of the interpolation coefficient $\lambda$, in various class conditions. Results without adaptation are obtained under the condition that the interpolation coefficient $\lambda$ is set at 0. In all the conditions, the recognition accuracy is improved by the adaptation. The best improvement of the mean accuracy, 2.3% in the absolute value, is achieved.
when $\lambda$ is 0.3 and the number of classes is 100. Although
the word-based adaptation method “w2gram” yields better
test-set perplexity than the class-based adaptation methods,
its recognition performance is the worst.

Figure 4 shows absolute percentage improvement of the
word accuracy for each presentation when the C-LM with
100 classes is used. Under the condition that the interpo-
lation coefficient $\lambda$ is less than 0.5, accuracy is improved
by the class-based adaptation for all the presentations. The
best improvement, approximately 6% in the absolute value,
is achieved for the presentation A05M0031 when $\lambda$ is 0.3.

4.1. Discussion

Figures 2 and 3 show that there is a discrepancy between
the improvement of the test-set perplexity and that of the word
accuracy. That is, the adaptation conditions with a large
number of classes which yield smaller test-set perplexity
do not necessarily achieve better recognition performance.

This is probably because the adaptation methods having a
large number of classes are over-tuned to the recognition
results including errors, and therefore, the contribution to
reduce the perplexity of correct hypotheses becomes less
significant.

Figure 4 shows the wide variety of improvement of recog-
nition accuracy among presentations. Figure 5 shows the
relationship between the improvement of recognition accu-
ry by the adaptation and the difference of perplexities be-
tween recognition hypotheses and correct transcriptions us-
ing the general language model, G-LM. Twenty presenta-
tions including the test set were used, and the number of
classes and the interpolation coefficient $\lambda$ were set at 100
and 0.3, respectively. There exists a clear correlation be-
tween the difference of the perplexities and the improve-
ment of word accuracy; its correlation coefficient is 0.76,
which is significant at a 0.1% significance level. The strong
correlation means that the proposed adaptation method is
more effective for presentations having a larger mismatch
with the G-LM.

5. CONCLUSION

This paper has proposed a batch-type unsupervised language model adaptation method using a class-based language model built based on recognition hypotheses obtained using a general word-based language model. The word classes are automatically determined by maximizing the average mutual information between the classes using a training set. The class-based model is linearly interpolated with the general language model and used for re-recognizing the speech. This method is effective in improving the word accuracy of spontaneous presentation speech recognition. Using a class-based language model having 100 classes, 2.3% improvement of word accuracy averaged over speakers in the absolute value has been achieved.

Future research includes automatic optimization of the number of word classes and the interpolation coefficient $\lambda$, and combination with acoustic model adaptation.
