# **Mechanical consequence observation and microscopic visualization of internal erosion using developed plane strain erosion apparatus**

**Mao Ouyang<sup>1</sup>, and Akihiro Takahashi<sup>2</sup>**

## **ABSTRACT**

Internal erosion has been frequently reported and has caused failures and instabilities of geotechnical structures. A plane strain erosion apparatus is developed in this study to allow the subsequent conduction of drained compression test after seepage test, and the microscopic observation of particle movement through a transparent window. A drained compression test preceded by a seepage test is performed on specimens containing the same initial fines contents to investigate the mechanical consequence impacts of seepage-induced internal erosion. Experimental results reveal that compared with uneroded soils, internally eroded soils show a larger secant stiffness at a small strain level (~1 %). At medium strain level (~15 %), the soils with erosion show smaller deviator stress comparing with soils without erosion. The analysis of images recorded by the microscope proves that the fines contacted with coarse particles possibly transferring the load are distinct between the soils with and without internal erosion at both small and medium strain levels during the drained compression test, which indicates that the soil fabric could affect the mechanical behaviors of soils subjected to internal erosion. Our designed equipment and microscopic observation could throw some light on the research of internal erosion from the view of particle scale.

## **Keywords**

Plane strain erosion apparatus; internal erosion; microscopy; stiffness; stress analysis; soil fabric.

## 1 Introduction

2 Evaluation of the safety of some geotechnical structures, such as embankments and dams,  
3 are often based on the assumption that the components of solid fracture are static. The changing  
4 climate has resulted in severe inundation and infiltration into the soils (Hirabayashi et al., 2013;  
5 Ouyang et al., 2020, 2021a,b), which has caused internal erosion and subsequent instabilities and  
6 failures (Foster et al., 2000). Internal erosion is defined here as the transport of detached finer  
7 particles through the soil mixtures under seepage flow (Bonelli, 2012), which would cause soils  
8 mass loss, volume change and hydraulic conductivity alteration from the viewpoint of macro-  
9 scale (Fannin and Slangen, 2014; Slangen and Fannin, 2017). Microscopically, internal erosion  
10 could lead to the transportation and local accumulation of fines within soil mixtures,  
11 mobilization of particles positions and change of the void volume (Fannin and Slangen, 2014;  
12 Slangen and Fannin, 2017; Ouyang, 2016). Elementary test apparatus has been developed to  
13 investigate the physical and mechanical features of internal erosion. Systematic visual  
14 observation has been employed to interpret the different mechanical consequences of soils with  
15 and without internal erosion.

16 Besides the studies performed to examine the criteria for soils likely to develop internal  
17 erosion (Kenney and Lau, 1985; Foster and Fell, 2001; Zhong et al., 2018), many experimental  
18 devices were developed and laboratory tests were conducted to understand the physical and  
19 mechanical behaviors of soils suffering internal erosion (Skempton and Brogan, 1994;  
20 Tomlinson and Vaid, 2000; Horikoshi and Takahashi, 2015). Xiao and Shwiyhat (2012)  
21 investigated the undrained behavior of internal eroded soils by triaxial apparatus with a revised  
22 pedestal to allow the dislodgement of fine fractions. Based on the hydraulic gradient changes  
23 during the internal erosion, Chang and Zhang (2011) divided the internal erosion into four

24 stages: stable, initiation, development and failure, by providing the pressurized seepage flow in a  
25 revised triaxial device. Ke and Takahashi (2014b) further revised the triaxial apparatus by  
26 supplying the back pressure into the sedimentation tank to ensure the high saturation degree of  
27 tested specimens experienced internal erosion. Except for the modified triaxial cells, Richards  
28 and Reddy (2010) developed a true triaxial piping test apparatus to evaluate the erosion potential  
29 of small to middle embankments. The true triaxial test results demonstrated that an increase in  
30 maximum principal stress and seepage angle and a decrease in the void ratio would cause an  
31 increase in the seepage velocity initiating the internal erosion (Richards and Reddy, 2012).

32 With the developed experimental apparatus, the mechanical consequences of soils  
33 subjected to internal erosion were reported. The triaxial drained compression tests on soils with  
34 and without erosion were conducted by Ke and Takahashi (2014a), results of which revealed that  
35 with the progress of internal erosion, the hydraulic gradient would decrease and hydraulic  
36 conductivity would increase. Further examination performed by Ke and Takahashi (2016)  
37 suggested that internal erosion could decrease the peak strength of cohesionless soils. Chen et al.  
38 (2016) performed drained compression tests on soils using the dissolved salt to represent the  
39 eroded fines. They reported that the peak friction angle and critical friction angle would decrease  
40 after fines losing, and the stress-strain response changed from dilative to contractive. Ouyang  
41 and Takahashi (2016a,b) compared the undrained compression behaviors of soils with and  
42 without erosion containing the same initial fines contents in a revised triaxial cell. They showed  
43 that the secant stiffness of soils with erosion was larger than that of soils without erosion at the  
44 small strain level. The undrained peak strength and residual strength were also changed by  
45 internal erosion. Similar results on specimens with a wide range of initial fines content were  
46 reported by Prasomsri and Takahashi (2020).

47           The experimental results have shown that the internal erosion would affect the physical  
48 and mechanical behaviors of soils, thus, many researchers tried to examine the differences from  
49 the systematic visual observations (Hunter and Bowman, 2018; Dumberry et al., 2018; Xie et al.,  
50 2018). The image subtraction approach was employed by Rosenbrand and Dijkstra (2012) to  
51 quantify the fines mobilization and transportation in a saturated plane strain porous medium. The  
52 results indicated that fines movement during internal erosion changes over time under constant  
53 flow boundary conditions. The transportation and removal of fines from the soils seemed to be  
54 localized due to the positive feedback effects. Ouyang and Takahashi (2015) optically quantified  
55 the feature of internal erosion in the plane strain physical models. They noted that fines were  
56 prone to be transported within an instant period of increasing hydraulic gradient, with few of  
57 them moving during the constant flow. The volume of specimens was reduced due to internal  
58 erosion, which resulted in an alteration of preferred coarse particle orientations in the observation  
59 field.

60           Numerical studies were also employed to interpret the effects of internal erosion on the  
61 soils mechanical behaviours. In terms of simulations within a discrete framework, the influence  
62 of confining pressure and fines content on the internal erosion of gap graded soils was  
63 investigated by a coupled CFD-DEM method (Liu et al., 2020). Zou et al. (2020) used a similar  
64 approach and noted that internal erosion caused a sharp reduction of fines in the bottom layer,  
65 while a slight decrease of fines in the upper layers. Yang et al. (2019b) proposed a four-  
66 constituent continuum model: solid skeleton, the erodible fines, the fluidized particles, and the  
67 pure fluid, to examine the effects of internal erosion on the safety of earthen structures. The  
68 erosion process was modeled based on the discharge of the fluidized particles (Yang et al.,  
69 2019c). To consider the soil's spatial variability, Yang et al. (2019a) introduced the random field

70 theory to investigate the internal erosion with randomly distributed initial porosity and fines  
71 contents. They reported that the assumption of soil homogeneity was insufficient to predict the  
72 decrease of the hydraulic conductivity during the internal erosion. A similar approach was  
73 employed by Yang et al. (2020), they compared the numerical simulation results with the  
74 experiment results, and mentioned that the specimens heterogeneity would affect the critical  
75 hydraulic gradient and delay of the final equilibrium state and more laboratory tests were  
76 beneficial for the further development of internal erosion modeling.

77 Although apparatus have been developed and techniques have been utilized to examine  
78 the characteristics of internal erosion, discovering the mechanism from the micro-scale/particle  
79 scale to the macro scale is still challenging. In this contribution, we develop a plane strain  
80 erosion apparatus equipped with a visible window to allow direct microscopic visualization and  
81 stress measurements in three directions. The drained compression tests are conducted in soils  
82 containing the same initial fines contents with and without seepage tests to show the effects of  
83 seepage-induced internal erosion on the physical and mechanical behaviors. An analysis based  
84 on the images recorded by the microscope is performed to explain the different mechanical  
85 behaviors from the perspective of particles contact.

86

## 87 Plane Strain Erosion Apparatus

### 88 **APPARATUS DEVELOPMENT**

89 To unravel the mechanical behavior of soils subjected to seepage-induced internal  
90 erosion, one of the main difficulties lies in the direct observation of particles movement and its  
91 relative positions during the seepage and compression tests. The other one is the application of  
92 surrounding stresses on the soils during the seepage tests since internal erosion often occurs in

93 geotechnical structures subjected to earth pressures. Moreover, a non-destructive approach is  
94 necessary for the quantification of the particles interface movement and the connection between  
95 the micro-scale behaviors and macro-scale consequences. Upon these difficulties, we develop a  
96 plane strain erosion apparatus, the schematic diagram of which is presented in Fig. 1. The  
97 photography of the main components of the plane strain erosion apparatus is shown in Fig. 2.  
98 The plane strain erosion apparatus is designed based on the revised triaxial erosion apparatus (Ke  
99 and Takahashi, 2014b) to microscopically observe the characteristics of internal erosion under  
100 plane strain conditions. Both seepage and drained compression tests can be performed in the  
101 developed equipment.

102         It mainly consists of a plane strain cell, a seepage control unit and a pressure control unit.  
103 A transparent acrylic window is assembled in the front of the plane strain cell to enable the  
104 tracking of particles transportation. Transparent membranes are employed in this research to  
105 enclose the soils.

106         The seepage control unit consists of a water reservoir, a flow pump and a sedimentation  
107 tank. The water reservoir is used to provide the water for the seepage test. The water is prepared  
108 at least 24 hours before conducting the experiments and is kept at room temperature. The  
109 seepage test performed in the developed plain strain apparatus is controlled by flow rate, because  
110 the application of flow rate in seepage-induced internal erosion could provide consistent results  
111 (Richards and Reddy, 2010). To maintain the constant flow rate during the seepage test, all the  
112 flow channels are designed to be the same size. The top cap is fabricated with a conical tough,  
113 and a perforated plate is mounted to be directly attached to the top surface of the specimen (Fig.  
114 3(a)). The pedestal is symmetrically made with an inverted conical tough and a perforated plate  
115 (Fig. 3(b)), to maintain the constant flow rate and minimize the water head loss. The opening

116 size of the perforated plate is 1 mm in this apparatus, which could fully hold the coarse particles  
117 and permit the dislodgement of fines (Ouyang and Takahashi, 2016a). The apertures are  
118 uniformly distributed in both the top cap and pedestal, plus that the specimen is enclosed by the  
119 flexible membrane, which could possible avoid some preferential flow that typically observed in  
120 the test using a fixed-wall permeameter along the transparent window. The eroded fine particles  
121 and the effluent water would be collected by the sedimentation tank (Fig. 1), which could be  
122 pressurized to simulate any reasonable downstream pressure or be open to the atmosphere. In  
123 this research, the downstream pressure is maintained at atmospheric pressure. The cumulative  
124 eroded soil mass is gained by continuously weighing the light tray, which is fully submerged in  
125 the sedimentation tank. During the trial test, we found that the fluid caused some impact effects  
126 on the light tray, which disturbed the measurement of the eroded mass. To minimize the  
127 influence, we put a funnel with a 15 mm diameter opening at the end of the inlet pipe. The  
128 position of the funnel outlet is aligned with the tray center. The miniature load cell installed in  
129 the sedimentation tank, which is waterproof and has a high sensitivity, could record the  
130 cumulative eroded soil mass within a continuous period. The theoretical capacity of the  
131 miniature load cell is 500 g; the precision of the miniature load cell is 0.01 g.

139 eroded soil mass, and the normal stress in the di<sub>yy</sub>). After the seepage  
140 test, the soil volume is measured to obtain the volumetric strain caused by seepage-induced  
141 internal erosion. For the drained compression tests, the axial stress, and soil deformation in both  
142 vertical and ho<sub>xx</sub>) are recorded.

### 143 **TESTED MATERIALS**

144 The tested specimens are 70 mm wide, 70 mm deep and 100 mm high. The materials are  
145 a mixture of blue-colored silica no. 8 and natural silica no. 3, which are mainly composed of  
146 quartz, and categorized as sub-round to sub-angular materials. Silica no. 3 has a large grain size,  
147 forming the skeleton of the soil specimens, which is regarded as coarse particles. Silica no. 8 is  
148 artificially coated with blue pigment, and then stabilized by baking. It is regarded as fines, which  
149 could be eroded by seepage flow in the gap-graded mixtures (Zuo and Baudet, 2015). All the soil  
150 mixtures are prepared with 25 % initial fines content by moist tamping method (Ladd, 1978)  
151 with the non-linear undercompaction criteria (Jiang et al., 2003), which has been proved to be  
152 able to generate uniform soil specimens in laboratory experiments (Ke and Takahashi, 2014b).  
153 The specimens are prepared with 42 % relative densities. The permeabilities of the specimens  
154 with 25 % initial fines content are  $2.4 \times 10^{-3} \text{ cm}^2$  (Freeze and Cherry, 1979; van Baaren, 1979).  
155 The properties of individual sand and mixed sands are shown in Table 1. The particle size  
156 distribution curves of soils based on the sieve test (ASTM D6913 / D6913M-17, 2017) are  
157 presented in Fig. 4, together with the microscopic image of particles. The image demonstrated  
158 that the contours of both fines and coarse particles can be observed by the microscope under the  
159 transparent membrane and acrylic window installed in the front of the plane strain erosion  
160 apparatus.

161 Base on the numerical analysis performed by Shire et al. (2016), and the experimental

162 work conducted by Lade et al. (1998) and Choo et al. (2018), the size ratio of D50/d40 can be  
163 regarded as a criterion to define the transition of soil fabric, where D50 is the coarse particle size  
164 with 50 % finer and d40 is the size of the fines with 40 % finer. When the size ratio of D50/d40  
165 was larger than 6, the soil mixtures could be regarded as gap-graded soils (Skempton and  
166 Brogan, 1994; Shire et al., 2016), where the contacts between fines and coarse particles depend  
167 on the fines content. In this study, the size ratio of the specimen equals 18, which presents a  
168 metastable transit state. The fines content was chosen as 25 %, which is smaller than the fines  
169 content where fines separate the coarse particles (35 %) (Shire et al., 2016). In this case, some  
170 fines carry reduced effective stress which might be transported by the seepage flow under  
171 appropriate conditions, and the mechanical consequences of the whole soils with and without  
172 internal erosion can be distinguished by the developed apparatus.

### 173 **EXPERIMENTAL PROCEDURE**

174 The experimental procedure of the plane strain erosion test includes saturation,  
175 consolidation, seepage, and drained compression tests. The stress path is shown in Fig. 5. The  
176 first number in the bracket means the horizontal normal stress perpendicular to the plane strain  
177  $\sigma_{xx}$  (the last number in the bracket means the vertical normal stress  $\sigma_{yy}$ ); the last  
178 number in the bracket means the vertical normal stress  $\sigma_{zz}$ ).

### 179 **Saturation**

180 The vacuum saturation procedure is employed in this study. Two separated reservoirs are  
181 connected to the top and bottom of the specimens. After soils preparation, vacuum is applied  
182 gradually until it reaches -20 kPa (equals to 20 kPa applied to the specimen in Fig. 5). In the test,  
183 a noticeable change of the particles arrangement by the vacuum pressure application was not  
184 observed, thus, we regard that -20 kPa vacuum pressure application would hardly cause the

185 modification of particles arrangement and void repartition from the initial state. Deaired water is  
186 then infiltrated into the soils from the bottom to the top. The velocity of flow is sufficiently slow  
187 ( $2.8 \times 10^{-5}$  m/s) to avoid the segregation of fines from the coarse particles. After around 10 times  
188 of the pore volume is flowed through deaired water, the saturation process is finished.

### 189 **Consolidation**

190 The consolidation is performed with a feedback control system.  $\sigma_{xx}$  is gradually increased  
191 up to the target value (50 kPa in this study) at a fairly low increment (1 kPa/min) to avoid the  
192  $\sigma_{zz}$ ), controlled by a motor, is programmed to be  
193  $\sigma_{xx}$  and is smoothly increased to 50 kPa (Fig. 5).

### 194 **Seepage Test**

195 Upon the finish of consolidation, the seepage test is conducted on specimens aiming to  
196 investigate the features of internal erosion. It is controlled by multistage flow rates based on the  
197 advantage of providing continuous flow within a relatively long period. The first to the third  
198 stage of the seepage test is terminated based on the criteria that within 600 s, 1) the effluence  
199 become clear and clean; 2) no further eroded fines could be measured; 3) no further specimen  
200 deformation could be measured; 4) no movement of particles could be observed by the  
201 microscope. The final stage (stage 4) is applied with the maximum capacity of the pump with  
202 flow rate equals to  $6.5 \times 10^{-6}$  m<sup>3</sup>/s, until all the water in the reservoir ( $5.3 \times 10^{-2}$  m<sup>3</sup>) are used in  
203 the seepage test, to allow more fines eroded away. The period of each stage is determined by the  
204 above criteria for the first experiment. In repeated case, the same period is employed, but some  
205 changes in the eroded soil mass are observed even near the end of stage 4. Figure 6 shows the  
206  
207 shown in Fig. 5). The cumulative eroded soil mass is recorded by the miniature load cell installed

208 in the sedimentation tank (Fig. 1). The microscopic images are recorded during each stage of  
209 seepage tests at various designed height by a microscope VCR-800 (Product by Hirox) (Ouyang  
210 and Takahashi, 2015).

### 211 **Drained Compression Test**

212 The drained compression test is displacement controlled with an axial strain rate  
213 increment of 0.1 %/min (in the direction of  $zz$ ) according to the standard criteria of the drained  
214 triaxial test (ASTM D7181-11, 2011). The stress-strain relationship and the axial strain against  
215 deviator stress are obtained from the drained compression test. During the compression tests, a  
216 series of microscopic images are recorded to investigate the movements and relative positions of  
217 both fines and coarse particles.

### 218 **TEST CONDITIONS**

219 The test conditions presented in this article are listed in Table 2. For the case name, PS  
220 means the plane strain test, CON means the consolidation test, WE and WOE represent with and  
221 without application of seepage test, respectively, N1 and N2 mean the number of tests. To  
222 examine the effectiveness of the preparation method, case PS\_CON is ended after the  
223 consolidation. Case PS\_WOE is performed to investigate the drained compression behaviors of  
224 soils without erosion. Seepage and subsequent drained compression test are conducted twice to  
225 validate the repeatability, corresponding to cases PS\_WE\_N1 and PS\_WE\_N2.

226

### 227 Experimental Results

#### 228 **OPTICAL RESULTS**

229 The photos of the whole specimens before, during, and after seepage test of case  
230 PS\_WE\_N2 are presented in Figs. 7(a), (b), and (c), respectively. The dislodgement of fines

231 could be clearly observed through the transparent membrane and acrylic window. Figure 7(d)  
232 shows the apparatus after the drained compression test, the specimen is compressed to around 15  
233 % axial strain. Two monotone microscopic images recorded at the same position before and after  
234 the seepage test are presented in Figs. 7(e) and (f), a comparison of which indicates that the fines  
235 are transported outside the scope of the microscope.

## 236 **SEEPAGE TEST RESULTS**

237 After the consolidation, the void ratios of soils in case PS\_CON are measured in five  
238 equivalent layers. The soils in each layer are oven-dried at 100°C for 24 hours. The targeting  
239 void ratio is 0.60, and the measured void ratios from the bottom to the top are 0.61, 0.53, 0.61,  
240 0.63, and 0.59. The good agreement between the measured void ratios and target void ratios  
241 suggests that specimens prepared by the moist tamping method with non-linear undercompaction  
242 theory could achieve reasonable homogeneity (Ouyang, 2016). A summary of seepage test  
243 results is shown in Table 3. After the seepage test, the vertical displacement of the top cap, and  
244 the average horizontal displacement of the water bladders which confined the soil specimen, are  
245 measured. The vertical displacement represents the vertical deformation of the specimen. The  
246 average horizontal displacement of the water bladders represents the horizontal displacement of  
247 the specimen in the  $x$  direction. The specimens show contractive behaviors in both vertical and  
248  $x$ ) directions. The vertical and horizontal displacements are 0.8 mm and 1.0 mm for  
249 case PS\_WE\_N1, and 0.9 mm and 0.9 mm for case PS\_WE\_N2. The void ratio increases,  
250 corresponding to a decrease of relative density, suggesting the specimens become loose after  
251 seepage tests.

252 The grain size distributions along the specimen after erosion are measured and presented  
253 in Fig. 8. To examine the spatial distribution of fines induced by internal erosion, the specimen is

254 divided into several parts. The illustration of the divided parts in the case PS\_WE\_N2 is shown  
255 in Fig. 8(a). The top, middle and bottom layers are divided equally to investigate the fines  
256 distribution along the length of the specimen. In each layer, two parts are divided, named T1, T2  
257 in the top layer, M1, M2 in the middle layer and B1, B2 in the bottom layer, in order to examine  
258 the influence of the boundary conditions. T2, M2 and B2 are the portions near the water  
259 bladders, which means they are subjected to flexible boundary conditions.

260 Figure 8(b) shows the particle size distribution curves in the top, middle and bottom  
261 layers. It can be observed that the fines distributions in these three layers are not the same, which  
262 suggests that the internal erosion would cause an inhomogeneous specimen under the plane  
263 strain condition. For the bottom layer, the particle size distribution curves of B1 and B2 parts are  
264 plotted in Fig. 8(c). It is noted that although in the same layer, the fines spatial distributions are  
265 affected by the boundary conditions. B2 part shows larger fines loss than B1 part, which means  
266 that the locations near the flexible boundary indicate larger fines loss than the other locations.

267 The evolution of  $\sigma_{yy}$  at the beginning 4,000 s  
268 for case PS\_WE\_N1 is shown in Fig. 9. It can be found that with the application of seepage flow,  
269  $\sigma_{yy}$  decreases. We can also note that the variations in  
270  $\sigma_{yy}$  correspond to the sudden increases of the cumulative eroded soil mass. This might be because  
271 that the seepage-induced fines transportation inside the soil matrix is not a uniform process due  
272 to the different sizes of particles and constrictions. Some fines might accumulate in the  
273 constrictions formed by coarse particles. When more and more fines are transported to these  
274 constrictions, the fluid impacts would increase. Some fines would be dislodged out to the  
275 sedimentation tank and measured by the miniature load cell when the force is larger than the  
276 capacity of the constrictions, which corresponds to the sudden increase of cumulative eroded soil

277 yy) presents a pulse  
278 shape, but it disappears after the sudden increase of eroded mass.

279 The evolution of the cumulative eroded soil mass during the whole seepage tests for cases  
280 PS\_WE\_N1 and PS\_WE\_N2 are shown in Fig. 10(a). Two cases showed similar trends in the  
281 progress of seepage tests and soil masses at the end of tests, suggesting the seepage tests  
282 performed by the developed planes train erosion apparatus could yield consistent results. Figure  
283 yy during the seepage tests. It is found that with the dislodgement  
284 of fines yy decreases correspondingly in this study. The permeability  
285 increases with the process of fines dislodgement, as demonstrated in Fig. 10(c).

286 The measurement during the experiments would include uncertainties, to examine the  
287 effects of the uncertainties on the results, we conduct the experiments with 25 % initial fines  
288 content twice. The measured total seepage-induced eroded soil mass and the decreasing trend of  
289 yy of the two cases are similar, which demonstrates that the repeatability of the developed plain  
290 strain apparatus is acceptable for this study.

## 291 **DRAINED COMPRESSION TEST RESULTS**

292 For the case PS\_WOE, the drained compression test is performed after the consolidation.  
293 For the cases PS\_WE\_N1 and PS\_WE\_N2, the drained compression tests are performed  
294 subsequently after the seepage tests. The relation of axial strain and volumetric strain during  
295 drained compression test is shown in Fig. 11(a). It is noted that both soils with and without  
296 erosion showed contractive volume deformation. During the seepage test, only the fines are  
297 eroded away through the perforated plate, the amount of coarse particles for the eroded and non-  
298 eroded are identical. At the medium strain level, fines might be pushed into the voids between  
299 coarse particles and the contacts between coarse particles dominant the volume of the specimens,

300 which probably lead to similar volumetric strains of eroded specimen compared with the non-  
301 eroded specimen (Zlatovic and Ishihara, 1997). The experiments performed by Ke and Takahashi  
302 (2016) also noted that the soils with and without seepage-induced internal erosion present quite  
303 similar volume changes during the drained compression tests.

304 Figure 11(b) presents the relationship between axial strain and deviator stress during the  
305 whole compression tests. The enlarged profile of axial strain between 0 and 2 % (Fig. 11(c))  
306 notes that when the axial strain was less than around 1 %, the deviator stress of soil with erosion  
307 is larger than that of soil without erosion at the same strain. This suggests that the seepage-  
308 induced internal erosion would affect the soil stiffness at a small strain level (Clayton, 2011).  
309 Secant stiffness is defined as the gradient of stress-strain curves, which reflects the relationship  
310 between the change of deviator stress and the change of axial strain. The normalized secant

311 xx,  
312 50kPa in this study). At the small strain level, the soil with erosion shows larger normalized  
313 secant stiffness than the soil without erosion, which suggested that internal erosion-induced soil  
314 fabric might cause the increase of secant stiffness at small strain level during drained  
315 compression (Ke and Takahashi, 2016). Taken the 0.1 % axial strain, for instance, the uneroded  
316 soil shows normalized secant stiffness of 50, whereas, the eroded soils show that of 90  
317 (PS\_WE\_N1) and 150 (PS\_WE\_N2), respectively. Due to the inherent limitation of the test

318 xx will wear the connection between the rubber water  
319 bladders and the steel plates, therefore, two post-erosion drained compression tests are ended at  
320 around 15 % axial strain. The peak strength here is then defined as the maximum value of the  
321 deviator stress. Table 4 shows the summary of drained compression test results of soils with and  
322 without erosion. The results reveal that the soils with erosion show smaller peak strength

323 compared with the soils without erosion in this study.

324

## 325 Discussions

326 The experimental results reveal that the mechanical behavior of soils with internal  
327 erosion is different from that of soils without erosion. The difference of stress responses changes  
328 with the levels of axial strain, which indicates that the explanation of the effects of internal  
329 erosion is much more complex than what we have perceived. Based on the assumption that the  
330 mechanical behaviors of sand mixtures are affected by void ratio and fabric (Zlatovic and  
331 Ishihara, 1997; Yang and Liu, 2016), the test procedures are reviewed and the corresponding  
332 microstructures of soils with and without erosion at key states are presented in Fig. 12. To  
333 compare the fines spatial distributions of eroded and uneroded soils, four key states are selected.  
334 For soils with erosion, the key states are WE\_A, the state before seepage test; WE\_B, state after  
335 seepage and before compression test; WE\_C, state at small strain level during drained  
336 compression test; and WE\_D, state at medium strain level (Fig. 12(a)). Correspondingly, the key  
337 states of soils without erosion are named WOE\_A, WOE\_B, WOE\_C, and WOE\_D (WOE\_A  
338 and WOE\_B are the same since seepage is not applied for the soils without erosion).

339 It was recognized that soil behaviors could be influenced by the preparation method  
340 (Takahashi, 2016). The microstructures in WOE\_A and WE\_A are derived from an original  
341 microscopic image taken in the center of the specimen, where coarse particles are represented as  
342 grey ovals, and fines are represented as black circles (Fig. 12(b)). The size of coarse particle in  
343 the schematic diagram is the same as that in the original image, whereas, the size of fines is  
344 exaggerated for a clear and reasonable demonstration of the transportation and contact. The  
345 specimens prepared by the moist tamping method are assumed to be in a metastable state, as

346 demonstrated by Sladen et al. (1985). This structure suggests that the fines are not simply to  
347 occupy the voids formed by coarse particles but lay around the contacts between coarse particles.  
348 For soils without erosion, during the drained compression test, the fines could be easily pushed  
349 away by the applied load due to the metastable state at the small strain level, as demonstrated in  
350 WOE\_C (Fig. 12(c)). At medium strain level (WOE\_D in Fig. 12(c)), the volume of specimens  
351 decreases, leading to a reduction of the void ratio. The reduction of void ratio would increase the  
352 contacts between coarse particles, indicated as more black and white solid lines between particles  
353 compared with WOE\_C; and would also probably result in a preferential orientation of contacts  
354 in the compression direction. These are responsible for the larger deviator stress at the medium  
355 strain level than that at the small strain level.

356 For soils with erosion, some fines are eroded during the seepage test, shown as dashed  
357 empty circles in WE\_B (Fig. 12(d)), resulting in an increase in the void ratio. The fines are  
358 moved internally to the contacts between coarse particles as well, which creates a unique soil  
359 structure. At the small strain level, these fines might transfer the load as shown in WE\_C (Fig.  
360 12(d)). At medium strain level, similar to that of soils without erosion, the decrease of volume  
361 and induced reduction of void ratio could lead to more contacts among particles (WE D in Fig.  
362 12(d)) and preferential contacts in the compression direction, which results in large deviator  
363 stress.

364 The influence of internal erosion on soils microstructures is examined through the  
365 comparison between WOE\_C and WE\_C; WOE\_D and WE\_D (Fig. 12). At the small strain  
366 level, the contacts between coarse particles are the same, whereas, the contacts between fines and  
367 coarse particles of soils with erosion are larger than those of soils without erosion (WOE\_C and  
368 WE\_C). It suggests that more fines might be accumulated around the contacts between coarse

369 particles, which could effectively transfer the load and then result in larger normalized secant  
370 stiffness for eroded soils comparing to that for uneroded soils. At the medium strain level, the  
371 contacts between coarse particles are also the same, but the contacts between fines and coarse  
372 particles of soils with erosion are smaller than those of soils without erosion (WOE\_D and  
373 WE\_D). It indicates that the fines in the contacts between coarse particles are smaller for soils  
374 with erosion than that for soils without erosion, which causes smaller peak strength for soils with  
375 erosion than that for soils without erosion.

376         The schematic discussions reveal that soil fabric, specifically the fines contacted with  
377 coarse particles and transferring the loads, is crucial in examining the influence of internal  
378 erosion on mechanical behaviors. A series of microscopic images of soils with and without  
379 internal erosion are recorded at different strain level sand is utilized to try to explain the different  
380 mechanical consequences caused by internal erosion. According to the simplifying assumption in  
381 the planar domain, the constriction size is defined as the largest sphere that will pass through a  
382 particular void formed by coarse particles (Silveira, 1965; Kenney and Lau, 1985). For the gap-  
383 graded soils, some fines could pass through within the constriction size, and the remaining fines  
384 might accumulate in the contacts between coarse particles, which are assumed to be able to  
385 transfer the loads. The area surrounded by coarse particles where fines possibly transfer the load  
386 is then calculated as the area of void confined by coarse particles subtracting the area of  
387 constriction size, which is termed as  $A_{\text{void}}$  in this study. The demonstration of  $A_{\text{void}}$  in terms of the  
388 densest and loosest state is shown in Fig. 13. The calculation of the coarse particle void and the  
389 constriction size is based on the assumption that the particles are sphere (Silveira, 1965; Kenney  
390 and Lau, 1985). The constriction size in the densest state is given by the largest circle which can  
391 be inscribed between three mutually touching particles (Fig. 13(a)). The constriction size in the

392 loosest state was given by the largest circle which can be inscribed between four touching  
 393 particles (Fig. 13(b)). The diameters of the coarse particle (silica no. 3) can be obtained from the  
 394 particle size distributions. Based on the diameters and the geometry, the void space and the  
 395 diameter of the inscribed circle are calculated.

396 Two factors would affect  $\alpha$ : particle size and relative density, as indicated in Fig. 14. The  
 397 soils with larger particle size and relative density would have larger contact areas. The effect of  
 398 particle size on the contact area is considered in the definition of constriction size. The influence  
 399 of relative density is accounted through a similar approach of constriction size (Indraratna et al.,  
 400 2007), which assumes that when the relative density equals zero, the distribution of  $\alpha$  is the same  
 401 as that in the loosest state. Thus,  $\alpha$  at a certain relative density is expressed as:

$$402 \quad \alpha = \alpha_{loosest} + \frac{\rho_r - 1}{\rho_r} \times (\alpha_{densest} - \alpha_{loosest}) \quad (1)$$

403 where  $\alpha$  is the chosen percentage of  $\alpha$ ,  $\rho_r$  is the relative density,  $\alpha_{loosest}$  is the area surrounded by  
 404 coarse particles where fines possibly transfer the load for a given value of the per cent smaller  
 405 than  $\alpha$ , and  $\alpha_{densest}$  is  $\alpha$  in the densest and loosest state, respectively, for the same  $\alpha$ . According to  
 406 Table 3, the eroded soils showed relative densities equal to 30 %, thus, the distributions of  $\alpha$  at  
 407  $\alpha$  equals 30 %, densest, and loosest states are shown in Fig. 15. It can be noted that the soils  
 408 show the largest  $\alpha$  at the densest state, whereas, smallest  $\alpha$  at the loosest state under otherwise the  
 409 same conditions. The controlling  $\alpha$  is chosen as 0.085 mm<sup>2</sup> for 20 % smaller in the distribution  
 410 curves (Indraratna et al., 2018), which is employed to compare the fines per cent in  $\alpha$  at small  
 411 and medium strain levels by the image analysis techniques.

412 The images of soils with and without erosion are recorded by the microscope at the  
 413 initiation, small and medium strain levels during the drained compression tests. Using one image  
 414 could be singular compared to the whole specimen, therefore, to prove our hypothesis (Fig. 12),

415 we employ more than 100 images in each case to obtain reasonable data. The fines per cent in  
416 is obtained through image segmentation and image subtraction algorithm (Ouyang and  
417 Takahashi, 2015; Ouyang, 2016). The fines contents of eroded specimens and the intact  
418 specimens are different at the beginning of the compression test, therefore, the soils images at  
419 both small and medium strain levels are subtracted by those at the beginning of the compression  
420 test in order to reduce the biases of image processes and to obtain reliable results, as shown in  
421 Fig. 16. With the progress of compression, fines are pushed away from their initial location,  
422 results in a reduction of fines percent in at both small and medium strain levels. Observation at  
423 a small strain level reveals that the percentage of fines in of soils with erosion is larger than  
424 that of soils without erosion. It suggests that more fines accumulated in the contacts between  
425 coarse particles possibly transfer the load, which results in larger normalized secant stiffness for  
426 the eroded soils than that for uneroded soils. At the medium strain level, the percentage of fines  
427 in of soils with erosion is smaller than that of soils without erosion. This might because the  
428 fines are transported into the voids created by internal erosion at the medium strain level, leading  
429 to a smaller percentage of fines, and further a smaller peak strength for soils with erosion than  
430 that for soils without erosion.

#### 431 **LIMITATION**

432 Whether the fines transferred load or not is difficult to be identified only through the  
433 relative positions between fines and coarse particles, which is an inherent limitation in discussing  
434 the soils mechanical behaviors through the image processing technique. Further development of  
435 advanced techniques is necessary to demonstrate the force chains in the granular materials. The  
436 area surrounded by coarse particles where fines possibly transfer the load is calculated through  
437 the images recorded parallel to the direction of compression load, whereas, fines dislodgement

438 and transportation also occur in the direction of seepage flow (Hunter and Bowman, 2018). Due  
439 to the limitation of the developed apparatus, it is difficult to record the images in the horizontal  
440 sections, which could be further improved with respect to the laboratory experimental  
441 equipment. here is defined in 2D planar, whereas, the soil particles are 3D spheres, which will  
442 lead to different distribution curves of . For instance, if the radius of a particle is 1, the confined  
443 planar area by three particles in the densest state is 0.16, the loosest state is 0.86; however, in 3D  
444 configuration, the confined volume is 0.68 in the densest state, 1.91 in the loosest state. It  
445 suggests that specific cautions are needed in the application of . It is admitted that the boundary  
446 would affect the fines movement in the seepage test. Although the transparent membrane is  
447 applied to provide a flexible boundary condition, fines could be more easily washed out nearby  
448 the boundaries than inside the sample (Nguyen et al., 2019). According to the measurement of  
449 the particle size distributions along the specimen, we find that the specimen would become non-  
450 homogeneous after seepage-induced internal erosion. The proposed schematic diagram could not  
451 represent the positions and transportation of both fines and coarse particles everywhere, hence,  
452 further research is necessary to examine the soil heterogeneity caused by internal erosion.

453

## 454 Conclusion

455 A plane strain erosion apparatus capable of directly investigating not only the mechanical  
456 behaviors of soils subjected to internal erosion but also the characteristics of internal erosion  
457 from the particle scale is developed. Repeated cases show similar results in the evolution of  
458 cumulative eroded soil mass and normal stress in the direction of plane strain, suggesting the  
459 developed apparatus could yield consistent results. During both the seepage and drained  
460 compression tests, soil specimens show contractive behaviors. The normal stress in the direction

461 of plane strain is found to decrease correspondingly to the dislodgement of fines. The soils with  
462 erosion indicate a different stress-strain relationship from the soils without erosion. The  
463 discussions on soil microstructures reveal that the soil fabric, specifically the fines accumulated  
464 in the area surrounded by coarse particles possibly transferring the load ( ), plays a crucial role  
465 in examining the mechanical consequence impacts of internal erosion. At the small strain level  
466 (~1 %), the soils with erosion show more fines percent in , which suggests more fines possibly  
467 involves in load transfer and then results in a larger secant stiffness, compared with the soils  
468 without erosion. At the medium strain level (~15 %), the percentage of fines in is smaller for  
469 soils with erosion than that for soils without erosion. This might due to fines transportation into  
470 the voids created by internal erosion, leading to a small peak strength for soils with erosion.
